Abstract

Branching Constraint Satisfaction Problems (BCSPs) have been introduced to model dynamic resource allocation subject to constraints and uncertainty. We give BCSPs a formal probability semantics by showing how they can be mapped to a certain class of Bayesian decision networks.

1 Introduction

Resource allocation is the problem of assigning resources to tasks subject to constraints, and has been studied in operations research and computer science for many years [1, 2, 8]. Recently, the problem has been investigated using constraint satisfaction methods [13], which allow arbitrary combinatorial constraints to be placed on the problem. In its simplest form, tasks can be represented by variables, and resources by values to be assigned to the variables, while constraints restrict the values that can be assigned simultaneously. A solution to a problem is then an assignment of values such that all constraints are satisfied. Initially, such approaches were restricted to deterministic, static problems; more recently it has been extended to problems that change over time, and for which there is some uncertainty about what the changes will be. *Branching Constraint Satisfaction* [5] has been proposed to model problems where new variables (or tasks) are added to the problem after some decisions have been made. The uncertainty in the sequence of additions is modelled by a transition tree with arcs labelled with probabilities. Branching CSPs are known to be NP hard [7]. Complete and incomplete optimising algorithms have been developed, using a combination of constraint-based tree search and decision-theoretic computation, and the methods have been compared to those used in Markov Decision Problems [6, 7]. However, the probability semantics of BCSPs were presented only informally.

*Also published as: Technical report TR0204, Department of Computing Science, University of Aberdeen, 2002.

Bayesian networks have been introduced as formalisms to represent and reason with joint probability distributions, taking into account conditional independence statements [11]. Given a Bayesian network and a (possibly empty) set of evidence concerning the variables included in the network, the probability distribution on any subset of variables can be computed. For this, efficient algorithms exist with fast, well-engineered computer implementations [9, 10], even though the problem of probabilistic reasoning in Bayesian networks is known to be NP hard in general [4]. However, reasoning with Bayesian networks for real-world problems is normally feasible. A Bayesian network can only be used for probabilistic reasoning; however, we can augment a network with decision theory, to obtain *influence diagrams* or *decision networks*, which can be used for decision-making under uncertainty [9, 12].

In this report, we study the relationship between branching CSPs, Bayesian networks and decision networks. Our aim is to establish the probability semantics by mapping BCSPs to decision networks. We will then consider how the techniques of decision networks may be used to generalise BCSPs, and, similarly, how BCSP methods might allow us to make explicit use of constraints in decision networks. In the next section, we introduce branching CSPs, and give a precise, formal definition. Next, we summarise Bayesian networks and decision networks. We then show BCSPs can be mapped to decision networks with a specific structure, and we prove that the optimal solutions to problems expressed in the different formalisms are equivalent.

2 Branching constraint satisfaction problems

2.1 Preliminary definitions

In the following, we borrow the terminology for graphs from [14]; if $S = (V, A)$ is a directed tree with set of vertices V and set of directed arcs $A \subseteq V \times V$, then the set of children of a vertex $v \in V$ is denoted by $\sigma(v)$; the unique parent of a vertex $v \in V$ is represented by $\pi(v)$. Furthermore, the *level* of a vertex v is defined as the length of the path from the root to v. The set of all vertices in the tree at the same level $n \in \mathbb{N}$ is denoted by $\lambda(n)$. The terminology will be generalised for acyclic directed graphs. Sets of elements will be represented by bold face letters, e.g. $\mathbf{V}$, if confusion may arise otherwise.

2.2 A motivating example

We first present a simple motivating example. A company has three workers, x, y and z, and five possible tasks, A, B, C, D and E that it may be asked to carry out. Each worker is qualified to do some of the tasks, as shown in Figure 1; each task is associated with a utility, representing the profit resulting from completing the task successfully. No worker can do more than one task. The company has some uncertain knowledge about the sequence of tasks it will be asked to perform, sketched as a probabilistic state transition tree in Figure 1. There will definitely be three tasks, and the first task to arrive will be A. Subsequently, either task B or C will arrive, with probabilities 0.6 and 0.4 respectively. If the second task is B, then the last task will be either D (with probability 0.5) or E (probability 0.5). If the second task is C, then the last task will either be D (0.5) or B (0.5). Some sequences of tasks may not be feasible for the company to do, and so it may choose to reject some tasks. The aim is to assign workers to tasks as soon as the tasks arrive, maximising the expected utility, while ensuring all constraints are satisfied.

	Tasks				
Staff	A	B	C	D	E
x	$\surd$	$\surd$	$\surd$	$\surd$	$\surd$
y	$\surd$	$-$	$-$	$-$	$\surd$
z	$\surd$	$-$	$\surd$	$-$	$-$
Utilities	3	6	10	6	6

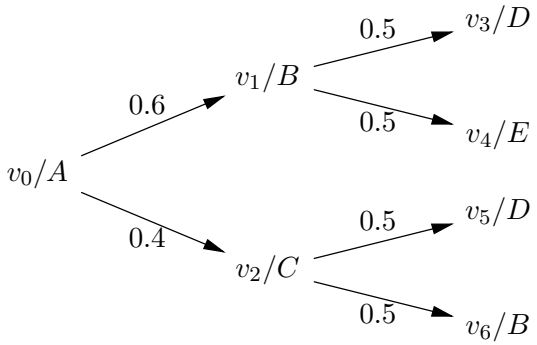

Figure 1: An example BCSP. *Left:* table of staff skills and tasks, with associated utilities for individual tasks; $\surd$ means that the task is suitable for the worker, and $-$ that it is unsuitable. *Right:* probabilistic state transition tree. An entry v/X indicates that variable X has been assigned to vertex v; numeric labels on the arcs indicate transition probabilities.

2.3 Formal definition

We give the formal definition of branching CSPs below. $\top$, or *null*, is a special value used to represent an explicit decision not to assign a value to a variable. An assignment of $\top$ to a variable will mean that any constraint on that variable will be satisfied by default.

Definition 1 *A* binary branching CSP *is a tuple* BCSP $= (X, D, \delta, C, U, S, \tau)$*, where*

- X *is a finite set of* variables*;*
- D *is a finite set of* values*, with function* $\delta : X \to \wp(D \cup \{\top\})$ *associating a* domain *of possible values to each variable* $x \in X$*, such that* $\top \in \delta(x)$ *for each* $x \in X$*;*
- C *is a finite set of binary* constraints*, where each* $c \in C$ *is a set of triples* (x, y, R)*,* $x, y \in X$*, and* $R \subseteq \delta(x) \times \delta(y)$ *such that* $\forall a \in \delta(x) \forall b \in \delta(y) : (\top, b) \in R$ *and* $(a, \top) \in R$*;*
- $U : X \times (D \cup \{\top\}) \to \mathbb{R}$ *associates a* utility *to each value* $w \in D \cup \{\top\}$ *assigned to a variable* $x \in X$*, with* $U(x, \top) = 0$ *for each* $x \in X$*;*
- $S = (V, A, \gamma)$ *is a probabilistic state transition tree with vertices* V *and arcs* A*; there is a distinguished vertex* $v_0 \in V$ *called the* root*, which has no parent; the function* $\gamma : V \times V \to [1, 0]$ *is defined such that* $\gamma(v, v') = 0$ *if* $(v, v') \notin A$*, and if* $\sigma(v) \neq \varnothing$*,* $\sum_{v' \in \sigma(v)} \gamma(v, v') = 1$*, for each* $v \in V$*;* γ *represents the conditional probability that vertex* v' *is the next to become active, given that the previous active vertex was* v*;*
- $\tau : V \to X$ *is a surjective function such that for any two vertices* v, v' *on the same path* p *in* S*,* $v = v'$ *if* $\tau(v) = \tau(v')$*. The function* τ *assigns a variable to each vertex, ensuring that no variable appears twice on a path from root to leaf.*

The probabilistic transitions are defined in terms of the vertices of the tree, and not directly in terms of the variables. Each vertex represents an *event*, and multiple different events may cause the same variable to become active. The probability of an event depends only on its immediate predecessor, and thus the problem obeys the Markov property.

Definition 2 *An* assignment *to a BCSP is a function $\varphi : V \to D \cup \{\top\}$ which assigns to each vertex either a value from the domain of its associated variable or the null value $\top$.*

Definition 3 *A* solution *to a BCSP is an assignment φ such that if v and w are vertices on a path in $S = (V, A)$ and $(\tau(v), \tau(w), R) \in C$, then $(\varphi(v), \varphi(w)) \in R$, i.e. φ satisfies all constraints appearing on a path.*

Note that a solution φ is a contingent solution, specifying an assignment to a variable dependent on the sequence of arrivals. In fact, the assignments are defined in terms of events (i.e. vertices of the tree), and not directly in terms of the variables. Further, the solution can be executed as the problem unfolds; the assignments are not dependent on subsequent developments of the problem. Thus the solution is a *policy*.

Definition 4 *Suppose when executing a solution, we are required to make an assignment at a vertex v_i at depth i in the tree. The* history $\mathbf{h}$ *for v_i is the sequence of assignments we made at vertices in the path from v_0 to v_i, and is the set $\{(v_0, x_0), (v_1, x_1), \ldots, (v_{i-1}, x_{i-1})\}$, where $v_{j+1} \in \sigma(v_j)$. If (v_i, x_i) does not violate any constraints when added to $\mathbf{h}$, then we write $(v_i, x_i) \propto \mathbf{h}$.*

Definition 5 *The* maximum expected utility *at a vertex v given its history $\mathbf{h}$ is the maximum, over non-conflicting decisions, of the utility of a decision plus the weighted sum of the maximum expected utility of the child vertices, given the extended history:*

$$\hat{U}(v \mid \mathbf{h}) = \max_{x \in \delta(\tau(v)) : (v,x) \propto \mathbf{h}} \left[U(\tau(v), x) + \sum_{v' \in \sigma(v)} \gamma(v, v') \hat{U}(v' \mid \mathbf{h} \cup \{(v, x)\}) \right]$$

Definition 6 *The* expected utility *of a solution to a BCSP is the expected utility of the root vertex in the solution. The expected utility of a vertex v in a solution, $\hat{U}_\varphi(v)$ is defined as*

$$\hat{U}_\varphi(v) = U(\tau(v), \varphi(v)) + \sum_{v' \in \sigma(v)} \gamma(v, v') \hat{U}_\varphi(v')$$

The goal of a BCSP is to find a solution with maximal expected utility. The maximal expected utility is thus $\hat{U}(v_0 \mid \varnothing)$.

Reconsider the example introduced above. Formulated as a branching CSP it holds that $X = \{A, B, C, D, E\}$, $D = \{x, y, z\}$, $\delta(A) = \cdots = \delta(E) = \{x, y, z, \top\}$, $U(x, \top) = 0$ for each $x \in X$, and for each $w \in D$: $U(A, w) = 3$, $U(B, w) = 6$, $U(C, w) = 10$, $U(D, w) = 6$, $U(E, w) = 5$, and the constraint set C consists of the following elements:

- $\langle A, B, \{(x, \top), (y, x), (y, \top), (z, x), (z, \top), (\top, x), (\top, \top)\}\rangle$
- $\langle A, C, \{(x, z), (x, \top), (y, x), (y, z), (y, \top), (z, x), (z, \top), (\top, x), (\top, z), (\top, \top)\}\rangle$
- $\langle A, D, \{(x, \top), (y, x), (y, \top), (z, x), (z, \top), (\top, x), (\top, \top)\}\rangle$
- $\langle A, E, \{(x, y), (x, \top), (y, x), (y, \top), (z, x), (z, y), (z, \top), (\top, x), (\top, y), (\top, \top)\}\rangle$
- $\langle B, C, \{(x, z), (x, \top), (\top, x), (\top, z), (\top, \top)\}\rangle$
- $\langle B, D, \{(x, \top), (\top, x), (\top, \top)\}\rangle$

- $\langle B, E, \{(x, y), (x, \top), (\top, x), (\top, y), (\top, \top)\}\rangle$
- $\langle C, D, \{(x, \top), (z, x), (z, \top), (\top, x), (\top, \top)\}\rangle$
- $\langle C, E, \{(x, y), (x, \top), (z, x), (z, y), (z, \top), (\top, x), (\top, y), (\top, \top)\}\rangle$
- $\langle D, E, \{(x, y), (x, \top), (\top, x), (\top, y), (\top, \top)\}\rangle$

The probabilistic state transition tree $S = (V, A, \gamma)$ with the definition of the function τ is according to Figure 1. The optimal solution is $\varphi(v_0) = y$, $\varphi(v_1) = x$, $\varphi(v_2) = z$, $\varphi(v_3) = \top$, $\varphi(v_4) = \top$, $\varphi(v_5) = x$, $\varphi(v_6) = x$, with expected utility $\hat{U}_\varphi(v_0) = 13.0$. Note that the task D is given a different allocation depending on the arrival sequence: it is rejected if it arrives in event v_3 (after B in v_1), but it is allocated worker x if it arrives in event v_5 (after C in v_2).

Note that the definition above is a slightly modified form of the one given in [6]. In that earlier paper it was assumed that the the utility function U did not distinguish between different values for a given variable (with the exception of $\top$); i.e. $U(x, v) = U(x, v')$ for each $v', v \in \delta(x)\backslash\{\top\}$. Also, in the probabilistic state transition tree, the sum of the transition probabilities for the children of a vertex was allowed to be less than 1. The missing probability represented the case where the parent event had no successor. In the definition given here, we could represent this by having a special variable whose domain is restricted to $\top$, and ensuring any vertex which activates this variable has no children.

3 Bayesian networks and decision networks

A *Bayesian network* $\mathcal{B}$ is a pair $\mathcal{B} = (G, P)$, where $G = (\mathbf{N}, A)$ is an acyclic directed graph with set of chance nodes $\mathbf{N}$, representing random variables, and set of arcs $A \subseteq \mathbf{N} \times \mathbf{N}$, representing statistical independence relationships among the variables [11]. Here we assume all random variables to be discrete. A joint probability distribution P is defined on the set of variables as follows:

$$P(N) = \prod_{X \in \mathbf{N}} P(X \mid \pi(X))$$

A Bayesian network allows for computing any a posteriori probability distribution of interest after entering evidence $\mathbf{e}$ into the network. In Bayesian network software packages, a posteriori probability distributions are computed from the marginal probability distribution of an updated probability distribution $P^{\mathbf{e}}$; for every (free) variable $X \in \mathbf{N}$, it holds that

$$P^{\mathbf{e}}(X) = P(X \mid \mathbf{e})$$

A *decision network* $\mathcal{D} = (G, P, \mathbf{N}, \mathbf{D}, \mathbf{W}, \mathbf{u})$, or *influence diagram*, is a Bayesian network with the addition of decision nodes $\mathbf{D}$ and utility nodes $\mathbf{W}$, standing for decision and utility variables, respectively. There is always a unique directed path in a decision network, on which every decision node D in $\mathbf{D}$ occurs, i.e. decision nodes are linearly ordered. Each utility variable W stands for a utility function $u_W : \delta(\mathbf{Z}) \to \mathbb{R}$, where $\delta(\mathbf{Z})$ is the Cartesian product of the domains of variables in $\mathbf{Z}$, and $\mathbf{Z} = \pi(W)$. The collection of utility functions is indicated by $\mathbf{u}$.

The aim of evaluating a decision network is to determine the optimal expected utility $\hat{u}$ for each decision d at a given decision node D, given the available evidence $\mathbf{e}$, which includes all previously made decisions. We assume a topological order of the nodes in the network, in

which we have combined consecutive nodes of the same type, and we place the utility nodes last. Thus we have $Y_0 \prec D_0 \prec Y_1 \prec D_1 \prec \cdots \prec D_{n-1} \prec Y_n \prec W$. We then define the maximum expected utility at a decision node D_i given some evidence $\mathbf{e}$ to be

$$\hat{u}_{D_i}(\mathbf{e}) = \max_{d_i \in D_i} \hat{u}_{Y_{i+1}}(\mathbf{e} \cup \{D_i = d_i\})$$

and at a chance node Y_i

$$\hat{u}_{Y_i}(\mathbf{e}) = \sum_{y_i \in Y_i} P(Y_i = y_i \mid \mathbf{e}) \hat{u}_{D_i}(\mathbf{e} \cup \{Y_i = y_i\})$$

In particular, we have the maximum expected utility over the whole network:

$$\hat{u}_{Y_0}(\varnothing) = \sum_{y_0 \in Y_0} P(Y_0 = y_0) \hat{u}_{D_0}(\{Y_0 = y_0\})$$

and for the terminating case we have:

$$\hat{u}_{Y_n}(\mathbf{e}) = \sum_{y_n \in Y_n} P(Y_n = y_n \mid \mathbf{e}) u_W(\mathbf{e} \cup \{Y_n = y_n\})$$

In diagrams of Bayesian networks and decision networks, chance nodes are indicated by circles or ellipses, decision nodes by boxes and value nodes by diamonds.

4 Relationship of branching CSPs to decision networks

4.1 Mapping branching CSPs to decision networks

Let BCSP $= (X, D, \delta, C, U, S, \tau)$. Below, we define the steps that make up the mapping from this representation to a decision network.

- For each set of vertices $\lambda(n)$ at level $n \in \mathbb{N}$ of the tree S, there is a chance node Y_n. The domain of the associated random variable Y_n is $\delta(Y_n) = \{v \mid v \in \lambda(n)\}$. The associated probability distribution P is defined by: $P(Y_n = u \mid Y_{n-1} = v) = \gamma(v, u)$ for $n > 0$, and $P(Y_0 = v_0) = 1$. Note that for two vertices $v \in \lambda(n-1)$ and $u \in \lambda(n)$ with $(v, u) \notin A_S$ we have that $P(Y_n = u \mid Y_{n-1} = v) = 0$, indicating that this transition cannot take place.

- Corresponding to each random variable Y_n with domain $\delta(Y_n)$, there is a decision node D_n, with domain equal to $\delta(D_n) = \{v.x \mid v \in \delta(Y_n), x \in \delta(\tau(v))\}$. There exists an incoming arc to each decision node from its associated chance node. In addition, the decision nodes are linked in a chain in an order reflecting the order of their associated chance nodes. The node will be used to assign values to its associated decision variable, which corresponds to assigning values to variable in the BCSP.

- For each chance node Y_n there is a corresponding utility node U_n. The parents of U_n are Y_n and the decision node D_n. If Y_n takes value v, and the decision node D_n takes any value $v.x$, $x \neq \top$, then the utility value is $U(\tau(v), x)$; otherwise it is 0. The utility nodes give their reward if a vertex (and hence a variable) has become active, and we have assigned a non-null value to that instance of the variable.

- For each pair of chance nodes (Y_i, Y_j) such that there are vertices $v \in \delta(Y_i)$ and $v' \in \delta(Y_j)$ with a constraint $(\tau(v), \tau(v'), R) \in C$, there exists a chance node $C_{i,j}$ with domain $\{t, f\}$ to represent the constraints on the corresponding decisions. The parents of $C_{i,j}$ are the decision nodes D_i and D_j. The probability distribution is defined as follows:

$$P(C_{i,j} = t \mid D_i = v.x, D_j = w.y) = \begin{cases} 0 & \text{if } (\tau(v), \tau(w), R) \in C \text{ and } (x, y) \notin R \\ 1 & \text{otherwise} \end{cases}$$

- There is one distinguished utility node U_C, whose parents are all the constraint chance nodes, with utility value 0 if all parents have value t, and utility value equal to $-M$ otherwise, where M is a penalty value larger than the sum of all utilities in the BCSP. This node ensures that the constraints are satisfied.

- Finally, for any given history in the execution of a BCSP solution, there is a corresponding evidence set for the network, defined by the function β below. Let $\mathbf{H}$ be the set of all possible history sets, and $\mathbf{E}$ be the set of all possible evidence sets. Then

$$\beta : \mathbf{H} \to \mathbf{E} : \mathbf{h} \mapsto \{Y_i = v, D_i = v.x : (v, x) \in \mathbf{h}, v \in \lambda(i)\}$$

Note that there are particular features of the mapping above, which can be exploited to simplify the utility calculations:

(1) Each variable Y_j is conditionally independent of each variable Y_k, $k = 0, \ldots, j-2$, and of each decision variable D_l given variable Y_{j-1}.

(2) The utility function u defined above for the utility nodes U_j is additive:

$$u(\tau(y_0), d_0, \ldots, \tau(y_m), d_m) = \sum_{i=0}^{m} U(\tau(y_j), d_j)$$

where y_j is a possible value of random variable Y_j and d_j is a possible value of decision variable D_j.

(3) We can create a topological order $Y_0 \prec D_0 \prec Y_1 \prec D_1 \prec \cdots \prec D_n \prec \mathbf{C} \prec \mathbf{W}$ where $\mathbf{C}$ represents the constraint chance nodes, and $\mathbf{W}$ represents the utility nodes. The initial node Y_0 has domain $\{v_0\}$, so the maximum expected utility of the network $\hat{u}_{Y_0}(\varnothing) = \hat{u}_{D_0}(Y_0 = v_0)$, and the utility function $u_W(\mathbf{e}) = \sum_{i=0}^{n} U(\tau(y_i), d_i) + u_C(\mathbf{e})$.

We can now simplify the utility definitions as follows:

$$\hat{u}_{D_i}(\mathbf{e}) = \max_{d_i \in D_i} \left[U(\tau(y_i), d_i) + \hat{u}_{Y_{i+1}}(\mathbf{e} \cup \{D_i = d_i\}) \right]$$

$$\hat{u}_{D_n}(\mathbf{e}) = \max_{d_n \in D_n} \left[U(\tau(y_n), d_n) + \hat{u}_C(\mathbf{e} \cup \{D_n = d_n\}) \right]$$

The $\hat{u}_C$ term in the second equation is simply the maximum expected utility from the constraint nodes. If any of the constraints evaluate to false, then the utility is $-M$. Otherwise, it is 0.

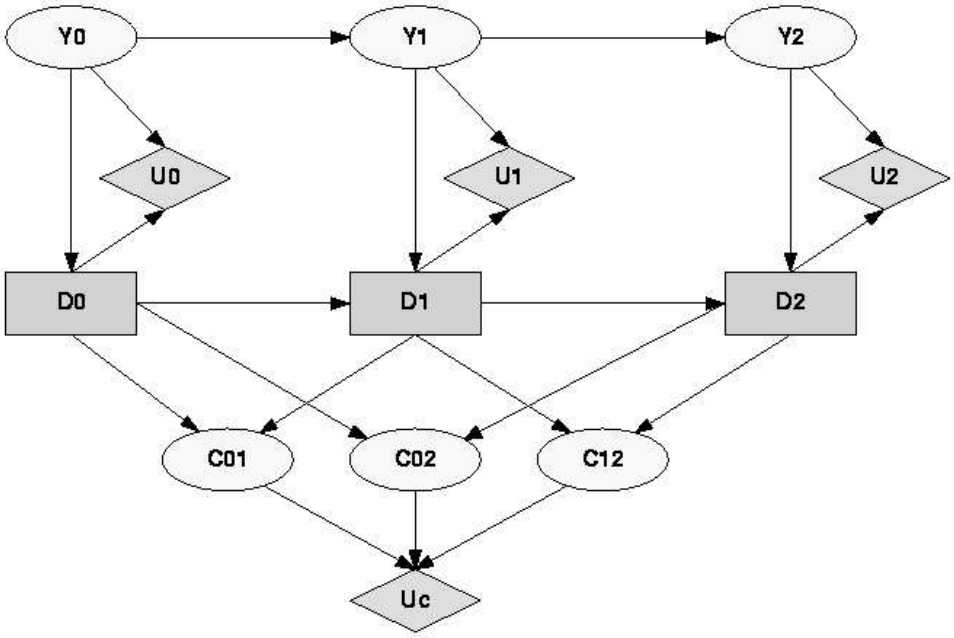

Figure 2: Decision network resulting from the mapping of the example BCSP.

The highest expected utility at the first decision node is equal to the optimal expected utility of the BCSP, and the optimal decisions of the decision nodes correspond to the optimal plan of the BCSP. We prove this in the next section.

The result of mapping the example BCSP discussed in Section 2 is shown in Figure 2. From the mapping designed above, it follows that the domain of the variable Y_0 is equal to $\{v_0\}$, for Y_1 it is equal to $\{v_1, v_2\}$; the domain of the decision variable D_0 is $\{v_0.x, v_0.y, v_0.z, v_0.\top\}$, and for D_1 it is equal to $\{v_1.x, v_1.\top, v_2.x, v_2.z, v_2.\top\}$.

4.2 Proof that the mapping is correct

We need to show that the optimal solution to the BCSP (i.e. the maximum expected utility at the root node) has the same value as the maximum expected utility of the first decision node in the network.

We will show that the maximum expected utility from any node in the tree given some history is the same as the maximum expected utility from the corresponding decision node in the decision network, given the corresponding evidence.

Theorem 1 *Let* $\mathcal{D} = (G, P, \mathbf{N}, \mathbf{D}, \mathbf{W}, \mathbf{u})$ *be the decision network corresponding to the* BCSP $= (X, D, \delta, C, U, S, \tau)$ *obtained by the mapping defined in Section 4.1, then for each node at level* k *it holds that:*

$$\hat{U}(v_k \mid \mathbf{h}) = \hat{u}_D(\beta(\mathbf{h}) \cup \{Y_k = v_k\})$$

Proof: We will prove the above by backwards induction on the depth of the node in the tree.

Basis Suppose v is a vertex in $\lambda(n)$, with n maximal depth. Then v must be a leaf vertex. It holds that

$$\hat{U}(v \mid \mathbf{h}) = \max_{x \in \delta(\tau(v)):(v,x) \propto \mathbf{h}} U(\tau(v), x)$$

and Y_n and D_n are its corresponding chance and decision nodes. For the decision network, v must be the value observed at chance node Y_n, so we have:

$$\hat{u}_{D_n}(\beta(\mathbf{h}) \cup \{Y_n = v\}) = \max_{d_n \in D_n} [U(\tau(v), d_n) + \hat{u}_C(\beta(\mathbf{h}) \cup \{Y_n = v, D_n = d_n\}]$$

By the definition of the penalty value, we only need to consider those d_n which do not violate the constraints. There will always be at least one, namely $v.\top$, and so the $\hat{u}_C$ term will be 0. Thus we have as required

$$\hat{u}_{D_n}(\beta(\mathbf{h}) \cup \{Y_n = v) = \max_{x \in \delta(\tau(v)):(v,x) \propto \mathbf{h}} U(\tau(v), x)$$

Induction hypothesis Suppose that

$$\hat{U}(v_j \mid \mathbf{h}) = \hat{u}_{D_j}(\beta(\mathbf{h}) \cup \{Y_j = v_j\})$$

holds for all vertices in the BCSP at levels $j = n, n-1, \ldots, i+1$.
Induction step Now consider a vertex v in the BCSP at level i. If v is a leaf, then the result is true by the basis argument. Now, suppose v is not a leaf, then it holds that:

$$\hat{U}(v \mid \mathbf{h}) = \max_{x \in \delta(\tau(v)):(v,x) \propto \mathbf{h}} \left[U(\tau(v), x) + \sum_{v' \in \sigma(v)} \gamma(v, v') \hat{U}(v' \mid \mathbf{h} \cup \{(v, x)\}) \right]$$

but v' must be a node at level $i+1$, so by the induction hypothesis

$$= \max_{x \in \delta(\tau(v)):(v,x) \propto \mathbf{h}} \left[U(\tau(v), x) + \sum_{v' \in \sigma(v)} \gamma(v, v') \hat{u}_{D_{i+1}}(\beta(\mathbf{h}) \cup \{Y_i = v, D_i = v.x, Y_{i+1} = v'\}) \right]$$

but since all $v_{i+1} \in Y_{i+1}$ with $v_{i+1} \notin \sigma(v)$ give a zero probability, and the decisions in D_i which give a non-negative utility are exactly those in $\delta(\tau(v))$ which satisfy the constraints in $\mathbf{h}$

$$= \max_{d_i \in D_i} \left[U(\tau(v), d_i) + \sum_{v' \in Y_{i+1}} P(Y_{i+1} = v' \mid Y_i = v) \hat{u}_{D_{i+1}}(\beta(\mathbf{h}) \cup \{Y_i = v, D_i = d_i, Y_{i+1} = v'\}) \right]$$

$$= \max_{d_i \in D_i} \left[U(\tau(v), d_i) + \hat{u}_{Y_{i+1}}(\beta(\mathbf{h}) \cup \{Y_i = v, D_i = d_i\}) \right]$$

$$= \hat{u}_{D_i}(\beta(\mathbf{h}) \cup \{Y_i = v\})$$

and thus we have proved the result by induction. □

As a corollary, we obtain that if the root node of the BCSP has an empty history, we can write $\hat{U}(v_0) = \hat{u}_{D_0}(Y_0 = v_0)$. Thus, we have proved the equivalence of the two representations of the problem.
